RESEARCH ARTICLE

Treatied with Proximal Femoral Nail Antirotation II

G Vinoth Kumar1, R Amarnath2, S Senthil Kumar3, B Thanigaiarasu4

ABSTRACT

Background: The treatment of intertrochanteric fractures continues to be a challenge in orthopedic trauma, especially in geriatric population. Among the various generations of cephalomedullary nails, proximal femoral nail antirotation II (PFN A-II) is specifically designed for Asian population, with helical blade, modified proximal diameter, and modified mediolateral angle.

Aim: The aim of this study was to analyze the functional outcome of patients treated with PFN A-II using Harris hip score, at our institution. The study included 20 patients (11 males and 9 females).

Results: Among the 20 patients included in the study, outcome was excellent in 5, good in 11, fair in 4, and this is based on Harris hip score with the minimum follow-up period being 6 months. The average union time was 13 weeks, average Harris hip score was 82.3. An abductor lurch was reported in one patient, postoperative thigh pain in two patients, infection in three patients, and bedsore in three patients.

Keywords: Asian population, Harris hip score, Helical blade, Intertrochanteric fracture, Proximal femoral nail, Proximal femoral nail antirotation II.

INTRODUCTION

Intertrochanteric fracture is one of the most devastating injuries whose incidence increases with advancing age. These patients are more limited to home ambulation and become dependent for doing their basic and instrumental activities of daily living. Fifty percent of fractures around hip in elderly patients involves trochanteric fracture that are of unstable type. They are usually complicated with associated comorbidities such as osteoporosis, diabetes, hypertension, and renal failure. In such circumstances, nonoperative treatment is mainly reserved for poor medical candidates and nonambulant patients with minimal discomfort after fracture. Today operative treatment has largely replaced conservative measures and the goal is to achieve accurate or acceptable treatment. Anatomical and stable reduction was performed with rigid internal fixation in order to achieve early mobilization of patients and prevent complications of prolonged recumbence. Despite marked improvements in implant design, surgical technique, and patient care, intertrochanteric fractures continue to consume a substantial proportion of our healthcare resources and remain a challenge to date. Complications with intertrochanteric fractures arise primarily from fixation rather than union or delayed union because the intertrochanteric area is made of cancellous bones.

The strength of the fracture fragment–implant assembly depends upon various factors including bone quality, fragment geometry, reduction, implant design, and implant placement. Among all these factors, surgeon can only modify the quality of the reduction, choice of implant, and its placement. A wide variety of treatment options are available for these fractures. The sliding hip screw device has been used for more than a decade for the treatment of these fractures, which may not be an ideal implant in all cases. Intramedullary load sharing device, namely, PFN, helps in early postoperative mobilization, weight-bearing, and ultimately the early fracture union. The proximal femoral nail antirotation II (PFN A-II) utilizes a helical blade instead of the conventionally used two screws. The helical blade is believed to provide stability, compression as well as rotational control of the fracture. Theoretically it compacts the bone during insertion into the neck and hence has higher cutout strength as compared to other devices. The differences are that the mediolateral angle is reduced from 6° to 5°. Hence, there is less chance of implant failure especially in elderly, osteoporotic bones. Thus, PFN A-II is a modification of the conventional PFN, which reduces even the minimal complications associated with conventional PFN and also provides additional advantages.

MATERIALS AND METHODS

A prospective study carried out at the Department of Orthopaedics, Government Royapettah Hospital and Kilpauk Medical College, Chennai, Tamil Nadu, India. Twenty patients were studied (21 hips—one patient had bilateral trochanteric fracture). The patients consisted of 11 males and 9 females whose age-group ranged from 45 to 85 years. Right femur was involved in 10 cases, left femur in nine patients, and bilateral in one patient. Mode of injury was road traffic accident in 10 patients and self-fall in 11 patients. Patients were classified based on Boyd and Griffin classification, fracture, with type II being predominant and type I being least. The classification was done based on the preoperative anteroposterior view with traction and internal rotation taken at the time of admission. The trauma to surgery interval was 3–7 days.

Inclusion Criteria

- Patients above 18 years of age presenting to our casualty with intertrochanteric femoral fractures with all Boyd and Griffin types (I–IV).
- Both displaced and undisplaced fractures
- Fractures of less than 1 week duration
- Without any other associated fractures

Exclusion Criteria

- Fractures with nonunion changes
- Old malunited intertrochanteric fracture
- Patients with arthritic changes in hip joint
- Pathological fractures

All patients were operated on the fracture table under spinal anesthesia after the routine preoperative assessment.

Postoperative Protocol

- Routine postoperative protocol and chest physiotherapy.
- Hip and knee mobilization from the first postoperative day.
- Weight-bearing increased in a graded manner.
- Perioperative deep vein thrombosis (DVT) prophylaxis with enoxaparin.
- Suture removal on 12th postoperative day
- Regular follow-up with periodic X-rays at 3rd and 6th months.

Patients were evaluated clinically and radiologically at 3 weeks’ interval for the first 3 months and thereafter monthly for the next 3 months and bimonthly for the next 12 months. During follow-up, the Harris hip score was evaluated at 3 and 6 months postoperatively, and the functional outcomes based on pain, function, absence of deformity, and range of motion were also assessed using Harris hip score. Collection of data was per the proforma with consent from patients.

Results

The time duration of surgery of the patients varied from 37 to 98 minutes. The number of fluoroscopy shots used during surgery was less than 10 shots in three patients, 10 to 15 shots in 13 patients, and more than 15 shots in five patients. The blood loss during surgery is also less in these patients, with less than 50 mL in one patient, between 50 mL and 100 mL in seven patients, between 100 mL and 150 mL in 12 patients, and more than 150 mL in one patient.

The Harris hip score grading was done and five patients were graded excellent, 11 as good, 4 as fair, and none as poor. The patient with bilateral trochanteric fracture was graded good. Among excellent, three patients were male and two female. Among good cases, seven were male and four were female, and among fair cases, one was male and three were female.

The type I fractures had excellent outcome; all type II had good outcome; and types III and IV had excellent, good, and fair outcomes. Radiographically the mean time for union was about 13.09 weeks. The time for union ranged from 12 to 16 weeks. The length of hospital stay varied from 5 to 24 days (with a mean of 11 days).

Complications

Bed sore occurred in three patients (one male and two female), superficial infection occurred in three male patients, which resolved with antibiotics, three patients had deep infection (two male and one female), which resolved with debridement and antibiotics, one female patient had abductor lurch, and in two patients (one male and one female) had postoperative hip pain. No cases of helical screw cutout, revision surgery, nonunion, or DVT were reported in our study.

Summary of Results

- Average operating time: 62.6 minutes
- Average blood loss: 130 mL
- Abductor lurch: 1 case
- Postoperative hip pain: 2
- Helical blade cutout: 0
- Average fracture union: 13.0 weeks
- Average image intensifier shots: 13.5 shots
- Average Harris hip score at 6 months: 82.3

See Figures 1 to 4.

Discussion

The PFN A-II is an effectively designed intramedullary load-sharing device. It incorporates the principles and theoretical advantages of the Zicker nail, dynamic hip screw, and locked intramedullary nail, with modifications for Asian population.

Biomechanically PFN A-II, just like the conventional PFN, is more stiff and has shorter moment arm, i.e., from the tip of helical blade to the center of femoral canal, whereas the DHS has a longer moment arm but undergoes significant stress on weight-bearing and hence higher incidence of lag screw cutout and varus malunion. The larger proximal diameter (17 mm) of the PFN A-II compared with PFN (15 mm) gives additional stiffness to the nail. Minimal blood loss, shorter operative time, early weight-bearing, less chances of implant failure, minimal fluoroscopy time, easier helical blade insertion (compared with cumbersome lag screw and derotation screw), less chances of postoperative hip pain, and better performance than any other implant in elderly osteoporotic patients are all the advantages of PFN A-II.

In the current study, the union rate was 100%. No cases of preoperative and postoperative femoral fractures were reported. No cases of varus malunion were reported.

The average blood loss in patients treated with the PFN A-II nail was 130 mL, ranging from 50 to 275 mL. The results were comparable with Karapinar et al.’s study7 (Table 1). Average operating time in our series was 62.6 minutes. In our initial cases, the operating time was on the higher range (range 43–82 minutes). With experience, the operating time reduced.

The operating time was more in types III and IV of Boyd and Griffin classification compared with other types.

Results were comparable to the series of Zhang et al.\textsuperscript{8} and Zhou et al.\textsuperscript{8} (Table 2).

The use of image intensifier was 13.5 shots in patients treated with PFN, which was comparable with the above-mentioned studies. In our study, it ranged from 8 to 20 shots. Fluoroscopy was more needed in types III and IV Boyd and Griffin classification.

In conclusion, the PFN A-II is a better implant with specific design superior to conventional PFN and also with distinct advantages over other implants to treat intertrochanteric fractures. With adequate surgical technique, the advantages of the PFN A-II increase and the complication rate decreases.
